;;;
John,

I am interested in what might be in the dissolved phase and capable to move to a nearby floodplain/alluvial pumping well.

Anything in the plume mix that might move conservatively indicating communication? The emergency monitoring has begun already.

Steve

Thanks Steve,

Unless I am missing something, this highlights a problem in having the proper data for fate and transport modeling. One of the most important measures (arguably most important) of impact and persistence from acid mine drainage is acidity, effectively the buffering capacity of the drainage to maintain a low pH when alkalinity is added. Acidity commonly is expressed in mg/L as CaCO₃ and is a function dominantly of dissolved Fe³⁺, Fe²⁺, Al³⁺, Mn²⁺ and pH.

Dissolved Fe³⁺, Fe²⁺ and Mn²⁺ are glaring omissions, as is the chemistry of the minepool. If there are no background data, this also is a problem. I think this area has ancient metasediments including carbonates as well as igneous. Judging from names I see in the area of the spill (Cement Creek and Soda Mountain (or Soda something)), the background creek chemistry might differ from the background Animus River, so backgrounds at each confluence might help as well.

In the dataset, I saw some pHs, only a few Al³⁺, some Fe without valence specified, and no Mn²⁺. Without some knowledge of these parameters, it is impossible to predict fate with the precision probably desired so far as I know.

John

PS: If someone wants to understand the data that is available, the spreadsheet that is on-line

needs to be reformatted and this would take a lot of time. As a first guess, each sample location on its own worksheet (ordered upstream to downstream), analytes across the spreadsheet (dissolved first, total last), dates listed down the spreadsheet chronologically). UNLESS: there are only a few dates, then swap the above analytes listed down and dates listed across.
